ABSTRACT: A large-pore version of Mg-CUK-1, a water-stable metal–organic framework (MOF) with 1-D channels, was synthesized in basic water. Mg-CUK-1L has a BET surface area of 2896 m² g⁻¹ and shows stark selectivity for CO₂ sorption over N₂, O₂, H₂, and CH₄. It displays reversible, multistep gated sorption of CO₂ below 0.33 atm. The dehydrated single-crystal structure of Mg-CUK-1L confirms retention of the open-channel structure. The MOF can be loaded with organic molecules by immersion in hot melts, providing single crystals suitable for X-ray diffraction. trans-Azobenzene fills the channels in a 2 x 2 arrangement. Solid-state UV–vis spectroscopy reveals that azobenzene molecules undergo reversible trans–cis isomerization, despite being close-packed; this surprising result is confirmed by DFT-simulated UV–vis spectra.

Hydrothermal synthesis of functional metal–organic frameworks (MOFs) using water as the only reaction medium is beneficial from an environmental perspective and provides MOFs that are inherently moisture-stable.¹ Their application as adsorbents for the capture of potable water in arid regions has been demonstrated by Yaghi and co-workers.² MOFs that resist hydrolytic decomposition also hold potential for applications in molecular separation/sequestration of wet feed-gas mixtures.³

The M-CUK-1 series of MOFs (⁴ M = Mg, Mn, Co, Ni) are prepared under sub-hydrothermal conditions (200–250 °C).⁴ They are based on 2,4-pyridinedicarboxylic acid (2,4-pdc; NC₆H₄-2,4-CO₂H) and have a 1-D channel micropore structure. Since their discovery in 2007,⁴b our group and others have shown that M-CUK-1 materials act as high-capacity and highly cyclable water adsorbents for adsorption-driven chiller applications⁴d and for H₂S capture.⁴e Compared to the d-metal analogues, Mg-CUK-1 utilizes a nontoxic metal, can be prepared rapidly at scale (30 min) using microwave-assisted heating, has a lower gravimetric density, and has a higher thermal stability (up to 450 °C).⁴a Mg-CUK-1 selectively adsorbs p-isomers from crude xylenes and divinylbenzenes; single-crystal X-ray diffraction (SCXRD) also permitted valuable structural resolution of p-isomer-loaded materials.⁴d

Given the versatility of Mg-CUK-1, we have applied an isoreticular approach⁵ to obtain a large-channel (“L”) version of Mg-CUK-1, which has a greatly increased surface area and is able to adsorb azobenzene (AzB) directly from a hot melt, resulting in X-ray quality crystals. Close-packed AzB in Mg-CUK-1L surprisingly undergoes reversible cis–trans isomerism.

The ligand 4-(4-carboxyphenyl)picolinic acid (cppH₂; C₆H₃N-2-CO₂H-4-(C₆H₄-4-CO₂H)) has the same coordinating moieties as 2,4-pdc but is extended by an extra phenyl ring at the 4-position. CppH₂ was obtained in gram quantities via Suzuki coupling followed by saponification of the dimethyl ester (Supporting Information). Precipitation with excess HCl yielded cppH₂ as the pyridinium hydrochloride salt. Co-dissolution of cppH₂·HCl with 1.5 equiv of Mg(NO₃)₂ in water containing 3 equiv of KOH resulted in an opaque white slurry, which was heated at 240 °C, yielding colorless crystalline rods of the target MOF.

Mg-CUK-1L ([Mg₃(μ₂-OH)₂(cpp)₂]·nH₂O) is isoreticular with the M-CUK-1 materials and crystallizes in the same monoclinic space group (C2/c; Z = 4). The asymmetric unit contains one complete cpp²⁻ ligand bound to two crystallographically unique Mg(II) centers (Figure 1A). The Mg(II) coordination modes include a five-membered N₅-C-chelate (N₁–Mg₁–O₁; Figure 1A) that allows cpp²⁻ to act as a linear linker akin to 4,4'-biphenyl, which yielded isoreticular versions of MOF-5.⁶ However, unlike the IRMOFs, the asymmetry of cpp²⁻ results in the channel walls of Mg-CUK-1L having a double-walled structure (Figure 1B). In the original M-CUK-1 series, these structural aspects were shown to impart enhanced mechanical and chemical stability.⁷

Mg-CUK-1L has accessible channel openings of 17.3 × 13.7 Å. Compared to Mg-CUK-1 (10.0 × 9.5 Å), the channels have a 2.5X greater cross-sectional area (237 vs 95 Å²; Figure 1C). The VOID utility in Platon¹ predicts an accessible volume of 2708 Å³ cell⁻¹, representing 56% of the cell volume. Thermogravimetric analysis (TGA) of as-synthesized Mg-CUK-1L unexpectedly showed no loss of crystalline framework.

CUK-1L revealed a mass loss of 18 wt % below 60 °C (Figure S1). Comparison to a predehydrated sample indicates that H₂O undergoes dynamic exchange with ambient moisture (Figure S1, inset). The unusually low dehydration temperature is indicative of hydrophobic microchannels. Cpp²⁻ is more hydrophobic than pdc²⁻, and the total amount of H₂O removed from Mg-CUK-1L was slightly less than for Mg-CUK-1. Between 65 and 480 °C Mg-CUK-1L lost no further mass (Figure S1); the large window of thermal stability is due to the highly electrostatic nature of Mg²⁺−O bonds. The TGA-derived mass loss corresponds to \( n = 7.3 \) H₂O. Combustion microanalysis was in close agreement, yielding \( n = 7.1 \). Solvent O atoms (Figure 1B) were also directly located in the electron difference map, yielding \( n = 9.5 \).

Attempts were made to dehydrate a single crystal of Mg-CUK-1L in situ on the diffractometer by increasing the temperature of the N₂ cryostream. This method provided the dehydrated structures of the original M-CUK-1 materials, but single crystals of Mg-CUK-1L fractured upon cooling. Instead, Mg-CUK-1L crystals were predehydrated at 80 °C under vacuum and subsequently used to collect SCXRD data for the dehydrated phase (Figure 2A and Supporting Information). This confirmed that Mg-CUK-1L resisted pore collapse upon dehydration; the material shows a concertina distortion in the crystallographic ab-plane compared to the fully hydrated structure (dimensions = 18.1 × 12.8 Å; Figures 2, S4, and Table S1), facilitated by changes in the Mg−O bond angles.

The cpp²⁻ ligand also offers greater solid-state flexibility compared with the parent CUK-1 series, based on rotation between the pyridyl and phenyl rings within the channel walls (dihedral angle change = +3.1°; from 28.5° to 31.6°). In line with the hygroscopic nature of Mg-CUK-1L, trace H₂O was always found in the channels upon crystal transfer to the diffractometer, corresponding to \( n = 1.25 \). 1/4-occupancy O atoms were located only near the channel walls. The porosity of Mg-CUK-1L was assessed by collection of adsorption–desorption isotherms between 0.02 and 0.95 atm. Crystalline samples were activated at 100 °C under vacuum overnight, and powder X-ray diffraction analysis (PXRD) confirmed that the bulk structure was retained upon activation and re-exposure to water (Figures S2 and S3). Mg-CUK-1L showed a clear sorption selectivity for CO₂ over all other gases studied (Figure 3). The maximum measured adsorption capacity for CO₂ was 17.5 mmol g⁻¹ at 196 K, corresponding to 56.6 wt %. The estimated BET surface area of Mg-CUK-1L based on CO₂ adsorption data was 2896 m² g⁻¹. The uptake of other gases was lower: 6.15 (CH₄; 196 K), 4.64 (H₂; 77 K), 4.23 (O₂; 77 K), and 2.37 mmol g⁻¹ (N₂; 77 K). At \( p/p₀ = 0.4 \), the molar sorption selectivity for CO₂/N₂ is 8.1 and that for CO₂/O₂ is 4.7. While the latter gases showed normal type-I sorption behavior, CO₂ displayed a multistep adsorption–desorption process with a pronounced hysteresis (Figure 3; blue data). At \( p/p₀ = 0.02 \)–0.33 the adsorption of CO₂ showed two distinct steps prior to saturation. The desorption hysteresis mirrored the adsorption steps, with a remanence of ca. 0.10.
This type of stepped sorption behavior has been observed in MOFs with larger, meso-sized pores and is commonly attributed to "gating effects", whereby a framework undergoes dynamic distortion upon loading and unloading. Long and co-workers recently exploited gated CH₄ sorption in a MOF to counteract the normal thermodynamic processes, thus obtaining a larger working capacity. The SCXRD structure of the dehydrated Mg-CUK-1L phase (Figure 2) indicates that a similar dynamic channel breathing effect is at play. In situ PXRD studies conducted at 0, 0.18, and 0.45 atm CO₂ loading (corresponding to the fully evacuated structure, before the onset of the first gating step, and at the onset of saturation, respectively) confirmed that the bulk material remained crystalline at each stage with a PXRD pattern corresponding to the fully dehydrated phase. However, upon exposure of the CO₂-loaded material to humid air for 1 h, the PXRD pattern corresponding to the fully hydrated material was recovered (Figure S4).

In an attempt to exploit the internal surface area of Mg-CUK-1L, we next studied the adsorption of larger liquid and solid hydrocarbons. Mg-CUK-1 was able to selectively adsorb p-xylene and p-divinylbenzene over mixtures of other isomers because the o- and m-isomers have larger critical diameters. The significantly larger channel openings in Mg-CUK-1 should permit entry of the larger isomers. Immersion of dehydrated crystals in o-xylene resulted in new high-angle reflections in the PXRD pattern (Figure S4). SCXRD analysis revealed that the channels were filled with o-xylene (Figure S5 and Table S1). Mg-CUK-1LC3(o-xylene) retained the same space group as the dehydrated material, and o-xylene molecules were packed based on host–guest π–π interactions, as well as short host–guest CH–π contacts (Figure S5).

On the basis of this encouraging result, we explored the application of Mg-CUK-1L as a host for the capture and crystallographic determination of large organic molecules. Fujita and Yaghi have demonstrated absolute configurational resolution of chiral organic molecules constrained inside MOF micropores. There is also interest in the isolation of photoisomerizable molecules inside MOFs to probe their properties in the solid state. Ruschewitz used MIL-68 to adsorb azobenzene ((C₆H₅N)₂) from vapor, but only achieved 30% loading. Zhou reported a MOF with azo linkages in the 3D framework that underwent reversible 30% loading. Zhou reported a MOF with azo linkages in the 3D framework, with no free space between the channel walls. The AzB molecules are closely packed in a 2 × 2 end-to-end arrangement (Figure 4B), with no free space remaining in the channels (Figure 4C).

Next, we assessed if photoisomerization to the cis form was hindered in the solid state. UV–vis spectra of hydrated Mg-CUK-1L revealed no absorption bands between 300 and 800 nm and a strong band below 250 nm corresponding to MOF-based metal–ligand charge transfer. Irradiation of the same sample at 320 or 460 nm for 60 s resulted in no spectral changes (Figure S7). In contrast, the UV–vis spectrum of the AzB-loaded material showed two characteristic absorbances at ca. 317.5 and 439 nm, corresponding to π → π* and n → π* transitions of AzB, respectively (Figures S8 and S9). Irradiation of Mg-CUK-1LC2AzB at 320 nm and collection of absorbance spectra at regular intervals revealed significant diminishment of the band at 317 nm after <30 s, accompanied by an increase in the band at ca. 439 nm due to cis-AzB (Figures S5A and S11). The observed "soft crystalline", flexible nature of Mg-CUK-1L allows the framework to accommodate the trans-to-cis conversion. Isomerization back to the trans state was achieved by irradiation at 460 nm for 30 s; the process was repeated over multiple cycles without loss of

![Figure 4.](image)

![Figure 5.](image)
integrated intensity, indicating full reversibility (Figure 5A; inset).

To further understand the trans–cis photoisomerization and to determine the origin of the loss of UV–vis response between 310 and 320 nm, DFT calculations were performed to model the optical transitions (Supporting Information). The calculated UV–vis spectra for cis- and trans-AzB molecules loaded in Mg-CUK-1L are in close agreement with the experimental observations (Figure 5B). DFT of the trans-AzB-loaded MOF predicted a characteristic absorption band at 295 nm that was diminished for cis-AzB, in line with the experimental findings. Independent UV–vis spectra calculated for isolated AzB molecules in both configurations (Figure S12) showed a strong response at 315 nm for trans-AzB corresponding to a π → π* transition; the same response was weak for cis-AzB.

The measured rate of thermal cis-to-trans relaxation of Mg-CUK-1LcAzB after irradiation at 320 nm at 298 K in the dark was slow (t_1/2 = 6.6 h; Figure S13). This enabled PXRD studies of the cis form immediately after irradiation at 320 nm, which revealed retention of crystallinity but no distinguishable differences in the bulk diffraction compared to the trans form. Furthermore, the simulated PXRD pattern for the cis-AzB form obtained from DFT studies is in excellent agreement (Figure S14). This is reasonable since the major reflections are due to the (ordered) host framework atoms.

Together with the DFT-predicted single-crystal structure of cis-AzB molecules in Mg-CUK-1L (Figure S15), it is apparent that trans-AzB molecules undergo reversible photoisomerization within the Mg-CUK-1L channels. Further studies using this material in water sorption and the sorption of chiral molecules are currently under way in our lab.
